# $^{68}\text{Ge}$ content quality control of $^{68}\text{Ge}/^{68}\text{Ga}$ -generator eluates and $^{68}\text{Ga}$ radiopharmaceuticals – A protocol for determining the $^{68}\text{Ge}$ content using thin-layer chromatography

Elisabeth Eppard, Natalia S. Loktionova, Frank Rösch\*

Institute of Nuclear Chemistry, University of Mainz, D-55128 Mainz, Germany

## HIGHLIGHTS

- $^{68}\text{Ga}$  is analytically separated from  $^{68}\text{Ge}$  using TLC.
- $^{68}\text{Ge}$ -breakthrough can be determined in  $^{68}\text{Ga}$ -eluate and radiopharmaceutical.
- $^{68}\text{Ge}$  breakthrough determination takes place within 1 h.

## ABSTRACT

$^{68}\text{Ge}$  breakthrough from a  $^{68}\text{Ge}/^{68}\text{Ga}$ -generator appears to be one of the most critical parameters for the routine clinical application of this generator and  $^{68}\text{Ga}$ -radiopharmaceuticals. We report a TLC-based (thin-layer chromatography) protocol which allows the  $^{68}\text{Ge}$  breakthrough of a generator to be determined within 1 h post-initial elution. The protocol can also be adapted to allow the  $^{68}\text{Ge}$  content of a  $^{68}\text{Ga}$ -radiopharmaceutical preparation to be determined prior to in vivo application.

## 1. Introduction

Commercially available  $^{68}\text{Ge}/^{68}\text{Ga}$ -generators offer initial activities of 0.74 (20 mCi), 1.11 (30 mCi), 1.85 (50 mCi) or more GBq of  $^{68}\text{Ge}$ . During the first few weeks of use, the  $^{68}\text{Ga}$  elution yield of these generators is typically 60–90%, which includes  $^{68}\text{Ge}$  breakthrough between  $10^{-2}\%$  and  $10^{-4}\%$  (Roesch and Riss, 2010; Loktionova et al., 2011). The breakthrough refers to the actual  $^{68}\text{Ge}$  content of the eluate, and is reported as the  $^{68}\text{Ge}$  activity in the eluate relative to that on the generator column (other values express this as the co-eluted  $^{68}\text{Ge}$  activity relative to  $^{68}\text{Ga}$  in the eluate (Breeman et al., 2011)). Many consider the problem of  $^{68}\text{Ge}$ -breakthrough to be one of the more significant challenges to the wider clinical acceptance and application of  $^{68}\text{Ga}$  and its generator.  $^{68}\text{Ge}$ -breakthrough is a sensitive parameter for  $^{68}\text{Ga}$ -radiopharmaceuticals considering the quality control requirements

governing their routine clinical application (Breeman and Verbruggen, 2007; Breeman et al., 2011). A recent report by Velikyan et al. proposed that the  $^{68}\text{Ge}$  content in a  $^{68}\text{Ga}$ -radiopharmaceutical is already below the toxic level for humans (Velikyan et al., 2013). In spite of this, current European Pharmacopeia Standards stipulate that the  $^{68}\text{Ge}$  content in generator eluate should not exceed 0.001% (European Pharmacopeia, 2013). Therefore, not only must  $^{68}\text{Ge}$  be removed, but a method is required to quantify the  $^{68}\text{Ge}$  content of a  $^{68}\text{Ga}$ -radiopharmaceutical.

$^{68}\text{Ge}$  decays exclusively via electron capture and is therefore only detectable (using radiochemical means) indirectly by the positron emission of its daughter nuclide,  $^{68}\text{Ga}$ . However, using this method it is not possible to detect  $^{68}\text{Ge}$  in the presence of an excess of  $^{68}\text{Ga}$ . Recently, we reported a protocol that allowed the  $^{68}\text{Ge}$  breakthrough to be isolated online, through the use of strong cation-exchanger resins, and quantified via the decay of its daughter radionuclide,  $^{68}\text{Ga}$  (Eppard et al., 2013). Using this protocol it was possible to determine the  $^{68}\text{Ge}$ -breakthrough within one (or 1/2) half-life of  $^{68}\text{Ga}$  after the initial elution.

E-mail address: [frank.roesch@uni-mainz.de](mailto:frank.roesch@uni-mainz.de) (F. Rösch).

For a “fresh” 1.11 GBq (30 mCi) generator, the  $^{68}\text{Ge}$  activity in the eluate is between 111.00 and 1.11 kBq (3000–30 nCi) (for breakthrough levels of  $10^{-2}$ – $10^{-4}\%$ ) within 0.67–1.00 GBq (18–27 mCi) of  $^{68}\text{Ga}$ . The eluted  $^{68}\text{Ga}$  decay according to Eq. (1) based on its half-life ( $t_{1/2}$  of  $^{68}\text{Ga}$ =67.71 min) is given as follows:

$$A_{\text{Ga}}^t = A_{\text{Ga}}^0 (e^{-\lambda t}) \quad (1)$$

Using  $\lambda = (\ln 2)/(t_{1/2})$  leads to

$$\ln(A_{\text{Ga}}^t) = \ln(A_{\text{Ga}}^0) - \frac{\ln 2}{t_{1/2}} t \quad (2)$$

$$\approx \ln(A_{\text{Ga}}^0) - 0.01t \quad (3)$$

where  $A_{\text{Ga}}^0$  =  $^{68}\text{Ga}$  activity immediately after elution and  $A_{\text{Ga}}^t$  =  $^{68}\text{Ga}$  activity at time  $t$  (in minutes) after elution, and  $\lambda = (\ln 2)/t_{1/2}$ .

The total  $^{68}\text{Ga}$  activity in the generator eluate is represented by both the eluted  $^{68}\text{Ga}$  decay and  $^{68}\text{Ga}$  generation from the co-eluted  $^{68}\text{Ge}$ . Thus, the equation is applied as follows:

$$A_{\text{Ga}}^t = A_{\text{Ga}}^0 (e^{-\lambda_{\text{Ga}} t}) + \frac{\lambda_{\text{Ge}}}{\lambda_{\text{Ga}} - \lambda_{\text{Ge}}} A_{\text{Ge}}^0 (e^{-\lambda_{\text{Ge}} t} - e^{-\lambda_{\text{Ga}} t}) \quad (4)$$

where  $A_{\text{Ge}}^0$  =  $^{68}\text{Ge}$  activity co-eluted (=breakthrough),  $A_{\text{Ga}}^t$  =  $^{68}\text{Ga}$  activity at time  $t$  after elution.

If there is no  $^{68}\text{Ga}$  present ( $A_{\text{Ga}}^0 = 0$ ) with the  $^{68}\text{Ge}$ -breakthrough (i.e.  $^{68}\text{Ga}$  in the eluate is removed), then Eq. (4) simplifies to Eq. (5). In this case increasing  $^{68}\text{Ga}$  activities are measured, due to decay of  $^{68}\text{Ge}$ -breakthrough, according to the secular radionuclide generator equilibrium (Rösch and Knapp, 2003)

$$A_{\text{Ga}}^t = A_{\text{Ge}}^0 (1 - e^{-\frac{\ln 2}{t_{1/2}} t}) \quad (5)$$

The saturation point or equilibrium is reached when

$$A_{\text{Ga}}^{\text{equ}} = A_{\text{Ge}}^{\text{equ}} \quad (6)$$

Therefore, the  $^{68}\text{Ga}$  activity from an initially pure  $^{68}\text{Ge}$  sample measured at 28.10 and 67.71 min will represent  $1/4$  and  $1/2$  of the total initial  $^{68}\text{Ge}$  activity, respectively. Therefore, it is possible to determine the amount of  $^{68}\text{Ge}$  present by multiplying the measured  $^{68}\text{Ga}$  activities at 28.10 and 67.71 min by a factor of 4 and 2, respectively.

For the quality control of  $^{68}\text{Ga}$ -radiopharmaceuticals, TLC is commonly used to analyze the labeling yield and product purity of  $^{68}\text{Ga}$  species based on the different  $R_f$  values of individual  $^{68}\text{Ga}$  species. Similarly, Ge(IV) and Ga(III) species may behave differently depending on the chosen stationary and mobile phases (Mirzadeh and Lambrecht, 1996). Provided that there is sufficient separation between the different species on a TLC plate, it is possible to determine the  $^{68}\text{Ge}$  content easily and quickly.

Of course, the  $^{68}\text{Ge}$  species is not visible directly after TLC plate development. It requires time to decay to its daughter radionuclide via electron capture before the positron emission of generated  $^{68}\text{Ga}$  is detectable. Thus, the  $^{68}\text{Ge}$  TLC ‘spot’ is allowed to develop for a known amount of time ( $1/4$  or  $1/2$  of a  $^{68}\text{Ga}$  half-life) to generate  $^{68}\text{Ga}$  before analyzing the TLC plate. ‘Spots’ pertaining to the different metallo-radionuclides are easily identified because the  $^{68}\text{Ga}$  species exhibits decreasing radioactivity, while the  $^{68}\text{Ge}$  species TLC spot increases in activity for  $\sim 10$  h past generator elution (assuming perfect separation of these species).

Fig. 1 shows a theoretical decay profile of a sample containing equal activities of  $^{68}\text{Ge}/^{68}\text{Ga}$  analyzed by TLC. The  $^{68}\text{Ge}$  and  $^{68}\text{Ga}$  species were assigned arbitrary  $R_f$  values of 0.2 and 0.8, respectively. The calculated activities of each spot are shown at  $t=0$ , 33.85 ( $1/2$  of a single  $^{68}\text{Ga}$  half-life) and 67.7 min (one  $^{68}\text{Ga}$  half-life) post-elution. There is a relationship between the rate at which  $^{68}\text{Ge}$  decays for the  $^{68}\text{Ge}$  spot and the initial  $^{68}\text{Ge}$  amount.

This approach can also be applied to determine the  $^{68}\text{Ge}$  content of a  $^{68}\text{Ga}$ -labeled compound, such as  $^{68}\text{Ga}$ -labeled

Fig. 1. Theoretical profile of a  $^{68}\text{Ge}/^{68}\text{Ga}$  sample at equilibrium analyzed by TLC. The  $^{68}\text{Ge}$  and  $^{68}\text{Ga}$  species are assigned arbitrary  $R_f$  values of 0.2 and 0.8, respectively. At  $t=0$ , there is no activity for the  $^{68}\text{Ge}$  spot and maximum activity for the  $^{68}\text{Ga}$  spot (=100%). [Note: this neglects nuclear transformations that occur during the TLC development and scanning ( $\sim 10$  min)]. Approximately 33.9 min later, a second scan detects  $^{68}\text{Ga}$  activity at the  $^{68}\text{Ge}$  species spot equal to 29% saturation (Eq. (2)), whereas the activity originating from the initial  $^{68}\text{Ga}$  spot ( $R_f=0.8$ ) decreases to 71% of its initial value. A final scan of the TLC plate at  $t=67.71$  min represents equal activities, i.e. the  $^{68}\text{Ga}$  activity detected at the  $^{68}\text{Ge}$  spot equals  $1/2$  of the initial  $^{68}\text{Ge}$  present.

Table 1

TLC mobile phases and  $R_f$ -values for  $^{68}\text{Ga}$ ,  $^{68}\text{Ge}$  and  $^{68}\text{Ga}$ -DOTATOC.

Mobile phase	$R_f$ -values		
	$^{68}\text{Ga(III)}$	$^{68}\text{Ge(IV)}$	$^{68}\text{Ga-DOTATOC}$
(a) 0.1 M citric buffer (pH=4)	1	1	0.1–0.2
(b) 5% NaCl:MeOH:25% $\text{NH}_3$ (3:1:1)	0	0.4–0.6	0.1–0.2
(c) 2 M HCl:acetone (1:1)	1	0.1	0.4

(e) Cyclohexanone:2 M HCl (20:1)	0.4–0.5	0.1	0

peptides, to determine  $^{68}\text{Ge}$  traces remaining in the final injectable solution. A TLC system capable of discriminating between the  $^{68}\text{Ge}$ , the  $^{68}\text{Ga}$ -radiopharmaceutical and uncomplexed  $^{68}\text{Ga}$ , is required. This approach may not be universal in terms of the conditions used for TLC, with different radiopharmaceuticals requiring tailor-made TLC systems. In this report  $^{68}\text{Ga}$ -DOTATOC, which is used for the diagnostic imaging of neuroendocrine tumors, was selected as a proof-of-principle study.

## 2. Methods

**$^{68}\text{Ge}/^{68}\text{Ga}$  generator:** A two-year old  $^{68}\text{Ge}/^{68}\text{Ga}$  generator (Eckert & Ziegler Strahlen- und Medizintechnik AG, Berlin, Germany) with a  $^{68}\text{Ga}$  yield of  $\sim 100$  MBq and  $^{68}\text{Ge}$  breakthrough of  $\sim 85$  kBq was used. The generator was eluted with 5 mL of 0.1 N HCl in all cases. Another generator was used as a source of  $^{68}\text{Ge}$  activity, and to obtain a stock solution of  $^{68}\text{Ge}/^{68}\text{Ga}$  at equilibrium (1.35 MBq  $^{68}\text{Ge}/^{68}\text{Ga}$  in 5 mL 0.1 N HCl).

**Synthesis of  $^{68}\text{Ga}$ -DOTATOC:** DOTATOC (21 nmol) was labeled using 0.4 mL of the  $^{68}\text{Ge}/^{68}\text{Ga}$  generator eluate (not post-processed) and 0.6 mL of 0.2 M  $\text{CH}_3\text{COONa}$  buffer (pH=4) for 10 min at  $95^\circ\text{C}$ . The  $^{68}\text{Ga}$ -labeled DOTATOC  $R_f$  value was determined for solvents a)–e).

**Thin-layer chromatography:** Table 1 shows the five mobile phases investigated for separating  $^{68}\text{Ge}$  and  $^{68}\text{Ga}$  on TLC plates (65 mm, Silica Gel 60 TLC strips, MERCK, Darmstadt, Germany).

The four mobile phases recommended by Mirzadeh and Lambrecht (1996), and the widely used 0.1 M citrate buffer (pH=4) were used. Freshly prepared solutions were used in all cases, which is especially important for mobile phases c) and e), due to self-condensation of the organic components.

For TLC analyses, 4  $\mu\text{L}$  aliquots from either the generator eluate or solution with the  $^{68}\text{Ga}$ -labeled product were spotted on TLC plates. Following TLC elution, the  $^{68}\text{Ge}$  and  $^{68}\text{Ga}$  distributions were detected using an instant-imager (Instant Imager<sup>®</sup>, Packard Canberra, Schwadorf, Austria) at 0, 1, 2, 3, 4, 5, 10, 15, 20, 25, and 30 h after TLC development.

**Radioactivity measurements:** For the quantitative analysis of low  $^{68}\text{Ge}$  activities, a sensitive detection system and short acquisition time are mandatory. Therefore, the detection limits of two different instant imagers (Instant Imager<sup>®</sup>, Packard Canberra and Rita Star<sup>®</sup>, Raytest-Isotopenmessgeräte GmbH, Straubenhardt, Germany) were investigated. Ten dilutions were made from a stock solution containing 0.118 MBq  $^{68}\text{Ge}$  in 5 mL (Table 2). The assessment was performed by spotting known activities of  $^{68}\text{Ge}$  on a cellulose strip and recording the  $^{68}\text{Ge}$  activity, using both imagers, after 10 and 30 min. For this aliquots 4  $\mu\text{L}$  were taken from each dilution and spotted on a single cellulose strip (150 mm  $\times$  10 mm). The cellulose strip was not developed.

### 3. Results and discussion

A TLC system to differentiate between  $^{68}\text{Ga}$  (30–50 kBq for this setup) and the relative small amount of  $^{68}\text{Ge}$  ( $\sim 34$  Bq for this setup) present in the generator eluate is required to allow the  $^{68}\text{Ge}$  content to be determined. With the exception of 0.1 M citrate buffer, all of the investigated mobile phases could be used to separate the  $^{68}\text{Ga}$  and  $^{68}\text{Ge}$  species on TLC plates. The recorded  $R_f$  values of the different species using each mobile phase are summarized in Table 1. Fig. 2 shows the positions of the  $^{68}\text{Ge}$  and  $^{68}\text{Ga}$  species on a TLC plate developed using mobile phase b). As expected, the measurements directly after TLC plate development almost exclusively show the initial  $^{68}\text{Ga}$  activity (not shown). To detect  $^{68}\text{Ge}$ , follow-up scans are required. These follow-up scans were recorded at 1 (L1), 10 (L2) and 24 h (L3) after TLC development.

While the activity of the  $^{68}\text{Ga}$  spot decreased, that of the  $^{68}\text{Ge}$  spot increased consistent with the generation, and subsequent decay, of its daughter radionuclide. The activity level 67.7 min after the TLC plate development represents half of the total  $^{68}\text{Ge}$  activity at the start. Therefore, using the calibration between absolute activity and observed count rate, it is possible to quantify the  $^{68}\text{Ge}$  breakthrough relatively quickly, i.e. approximately 1 h after generator elution or labeling.

When this protocol is applied to determine the  $^{68}\text{Ge}$  content of a prepared radiopharmaceutical, the chosen TLC system should

provide sufficient separation of  $^{68}\text{Ge}$  species, uncomplexed and complexed  $^{68}\text{Ga}$  (the radiopharmaceutical). In the case of  $^{68}\text{Ga}$ -DOTATOC, which can be prepared with a radiochemical yield of 99%, this translates to activity ratios of 1:100:10,000 for the three species. As shown in Fig. 3, mixtures b), c) and d) were most suitable for the resolution of  $^{68}\text{Ga}$  (L1),  $^{68}\text{Ga}$ -DOTATOC (L2) and  $^{68}\text{Ge}$  (L3), respectively.

Fig. 4 depicts a population distribution map of a TLC plate, spotted with a solution containing  $^{68}\text{Ga}$ -DOTATOC and  $^{68}\text{Ge}$  (0.5 mL of stock solution), imaged at 0, 2, 4 and 6 h after TLC development with mobile phase c). The activity of the  $^{68}\text{Ga}$ -DOTATOC spot ( $R_f=0.4$ ) decreased at a rate corresponding to the  $^{68}\text{Ga}$  half-life. In parallel, the  $^{68}\text{Ge}$  spot ( $R_f=0.1$ ) showed an increasing count rate, corresponding to the half-life of  $^{68}\text{Ge}$  generation in situ. The calibration between the observed activity (on the TLC) and the absolute activity of  $^{68}\text{Ge}$  allowed the  $^{68}\text{Ge}$  content in the  $^{68}\text{Ga}$ -DOTATOC sample to be quantified 1 h after labeling.

The Packard Canberra Instant Imager<sup>®</sup> detected  $^{68}\text{Ge}$  levels as low as 5.90 and 2.95 Bq ( $10^{-16}$  mol) after 10 and 30 min, respectively. By comparison, the Raytest-Isotopenmessgeräte GmbH Rita Star<sup>®</sup> was considerably more sensitive, detecting activities of 0.74 and 0.36 Bq ( $10^{-17}$  mol) at the same time points. For each imager, linear regression was used to determine a unique linear calibration equation, which allows the  $^{68}\text{Ge}$  content to be quantified (Fig. 5).

The linear regression from the Instant Imager<sup>®</sup> (Packard Canberra) calibration, after 10 min measurement, yields the following equation:

$$y = 2.6344x + 0.4167 \quad (7)$$

$$x = \frac{y - 0.4167}{2.6344} \quad (8)$$

where  $y$ =counts per minute measured over 10 min and  $x$ =activity in Bq spotted onto the TLC plate.

4  $\mu\text{L}$  sample from the initial  $^{68}\text{Ga}$  eluate was spotted onto a TLC plate and developed with mobile phase b). Fig. 6a shows the TLC measured directly after development. Uncomplexed  $^{68}\text{Ga}$  remains at the starting point ( $R_f=0$ ). The TLC was then cut at  $R_f=0.3$  and the upper section re-measured for 10 min (Fig. 6b). The upper section contains the  $^{68}\text{Ge}$  species, and is detected via the decay of its daughter radionuclide. The measured value for counts per minute is inserted in Eq. (8), which leads to value of 12.75 Bq  $^{68}\text{Ge}$  in 4  $\mu\text{L}$  aliquot, which corresponds to 15.93 kBq  $^{68}\text{Ge}$  in the initial eluate (5 mL). Inserting this value into Eq. (5) gives the absolute  $^{68}\text{Ge}$ -breakthrough in the initial eluate as 147.83 kBq.

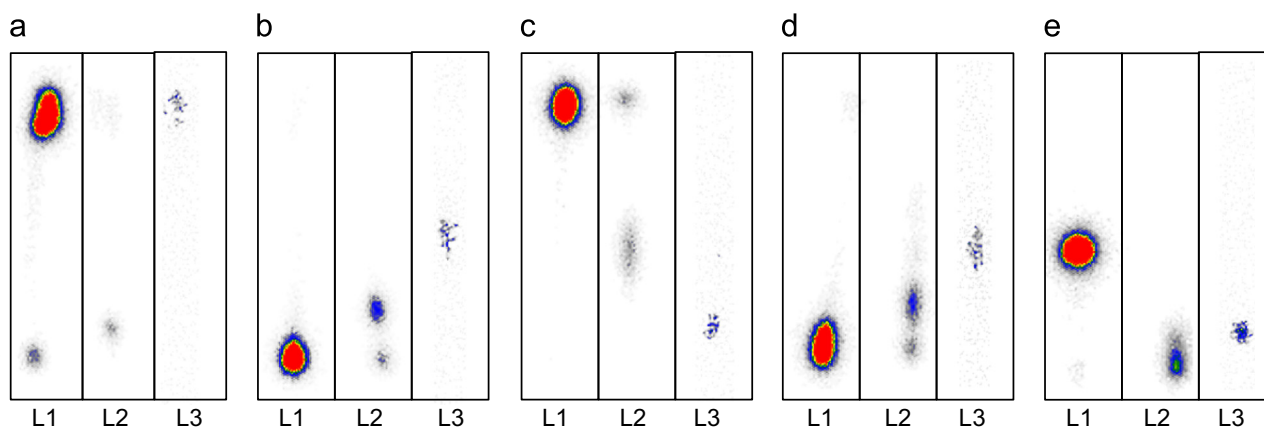

Fig. 3. TLC plates developed using mobile phases (a)–(e) (Table 1). Lanes: L1= $^{68}\text{Ga}$ ; L2= $^{68}\text{Ga}$ -DOTATOC and uncomplexed  $^{68}\text{Ga}$ ; L3= $^{68}\text{Ge}$ .

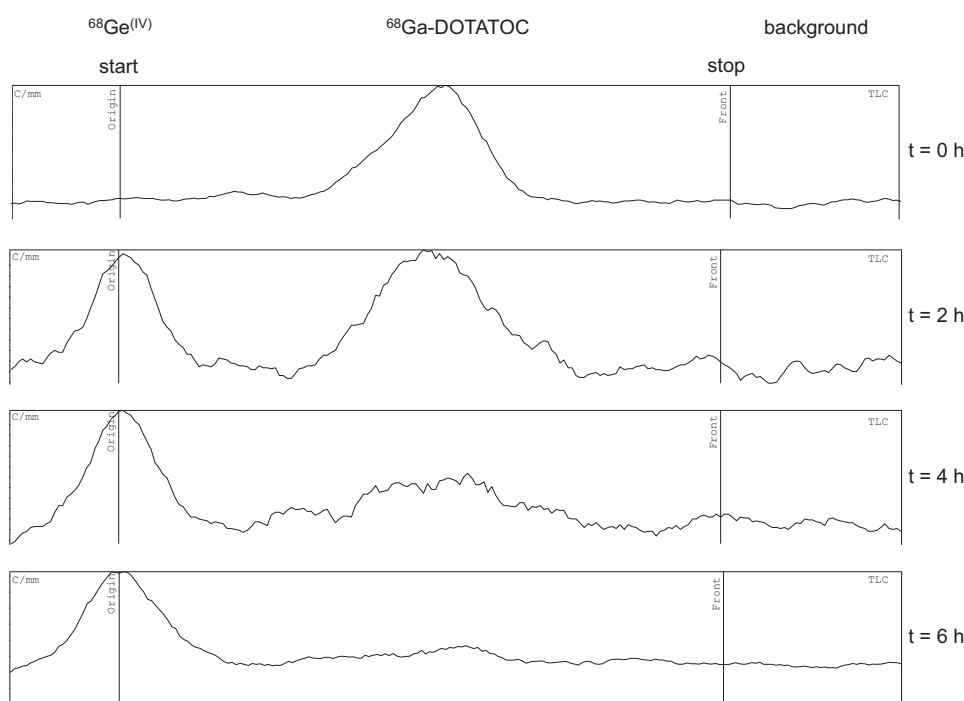

Fig. 4. TLC analysis of a  $^{68}\text{Ga}$ -DOTATOC preparation developed using the TLC solvent mixture (c), 2 M HCl/acetone (1:1) and measured at 0, 2, 4 and 6 h after development. The y-axis represents the maximum relative count-rates.

To evaluate the usefulness of this protocol for determining the  $^{68}\text{Ge}$  content of a  $^{68}\text{Ga}$ -DOTATOC preparation, 1 mL solution of the radiopharmaceutical was spiked with 0.4 mL of the  $^{68}\text{Ge}$  stock solution. 4 mL aliquot was spotted onto a TLC plate and developed using mobile phase d). Due to regular fluctuations in the  $^{68}\text{Ge}$  breakthrough and dilution effects, a known amount of  $^{68}\text{Ge}$  was added to the  $^{68}\text{Ga}$ -DOTATOC solution instead of measuring the  $^{68}\text{Ge}$  breakthrough directly.

Fig. 7a shows the entire TLC plate scanned immediately after development.  $^{68}\text{Ga}$ -DOTATOC remained near the starting point at  $R_f=0.1$ . The TLC plate was then cut at  $R_f=0.3$ – $0.35$ , and scanned for 10 min (Fig. 7b) to measure the activity resulting indirectly from spotted  $^{68}\text{Ge}$ . The measured counts per minute was inserted into Eq. (8) to give a  $^{68}\text{Ge}$  content in 4  $\mu\text{L}$  aliquot of 106.42 Bq. Using the dilution factor this translates to an initial  $^{68}\text{Ge}$  content of 37.25 kBq in the 1 mL  $^{68}\text{Ga}$ -DOTATOC solution.

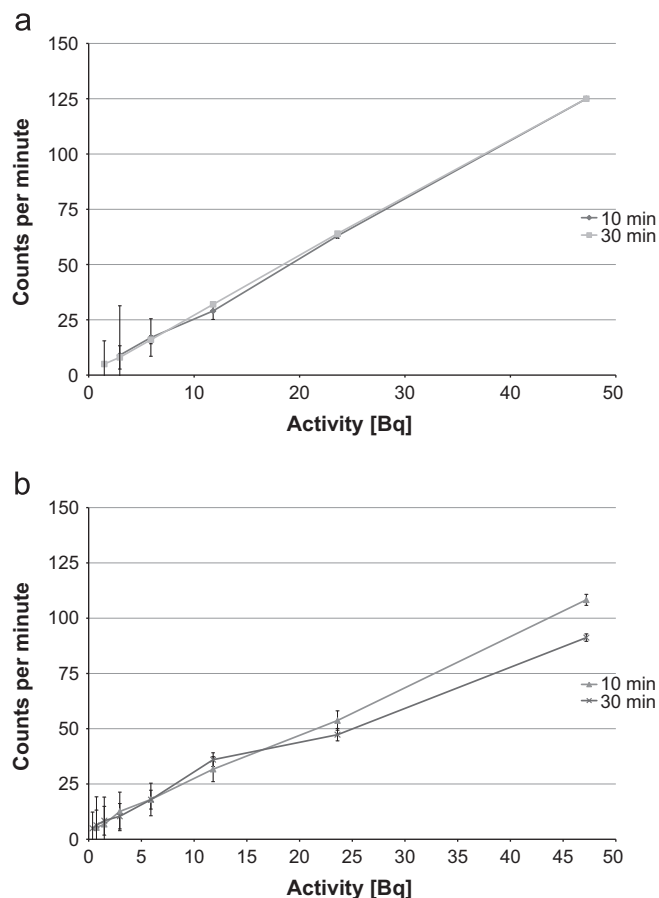

The actual  $^{68}\text{Ge}$  breakthrough contained in the original  $^{68}\text{Ga}$ -DOTATOC solution is 1.41 kBq, which was calculated by subtracting

the  $^{68}\text{Ge}$  spike (35.84 kBq) from the actual  $^{68}\text{Ge}$  content. Inserting this value into Eq. (5) gives an absolute  $^{68}\text{Ge}$  content of 13.01 kBq.

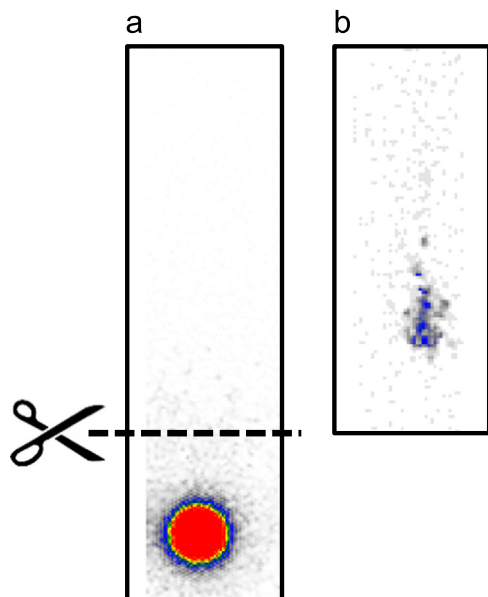

The  $^{68}\text{Ge}$  breakthrough in the generator eluate and  $^{68}\text{Ga}$ -DOTATOC solution was determined under standard conditions. The overall protocol, which includes TLC development and measurement, takes less than 30 min. Therefore, it is possible to quantify the  $^{68}\text{Ge}$  content in a generator eluate or radiopharmaceutical preparation prior to their further application.

#### 4. Conclusions

A TLC based protocol has been developed which allows the  $^{68}\text{Ge}$  content of generator eluates and  $^{68}\text{Ga}$ -DOTATOC preparations to be determined half an hour after TLC development. The method relies on the resolution of the  $^{68}\text{Ge}$  and  $^{68}\text{Ga}$  species on TLC with  $^{68}\text{Ge}$  quantification made possible via the decay of its daughter radionuclide. This novel protocol allows for the rapid and reliable

**Fig. 5.** Calibration of the  $^{68}\text{Ge}$ -breakthrough quantification for the a) Instant Imager<sup>®</sup> (Packard Canberra) and b) Rita Star<sup>®</sup> (Raytest – Isotopenmessgeräte GmbH) after 10 and 30 min duration measurements.

**Fig. 6.** TLC analysis of the initial eluate developed using the mobile phase (b), 5% NaCl:MeOH:25%  $\text{NH}_3$  (3:1:1) and measured (a) directly after TLC development and (b) directly after cutting the TLC at  $R_f = 0.3$ .

determination of  $^{68}\text{Ge}$  activity levels in a  $^{68}\text{Ge}/^{68}\text{Ga}$ -generator eluate without the use of  $\gamma$ -spectroscopy. The protocol may also

**Fig. 7.** TLC analysis of  $^{68}\text{Ga}$ -DOTATOC preparation (containing  $^{68}\text{Ge}$  spike) developed in mobile phase (d), 0.01 M  $\text{NaC}_4\text{H}_9\text{O}_6$ :MeOH (3:1), measured (a) directly after TLC development and (b) directly after cutting the TLC plate at  $R_f = 0.3-0.35$ .

suitable for the quality control for  $^{68}\text{Ge}$  content of individual radiopharmaceutical preparation. This has been demonstrated for  $^{68}\text{Ga}$ -DOTATOC, where the  $^{68}\text{Ge}$  content can be determined prior to administration of the radiopharmaceutical. Therefore, this novel protocol permits the analytical quantification of the  $^{68}\text{Ge}$  content in a  $^{68}\text{Ge}/^{68}\text{Ga}$ -generator eluate and  $^{68}\text{Ga}$ -radiopharmaceutical within a time frame suitable for their further application.
